Chapter 1

Introduction

PEBCAK [1]: Problem exists between chair and keyboard. This quote is frequently used to explain that many problems come from the user. Unfortunately, users do not always have an advanced knowledge in computer science. Beyond user's lack of knowledge on computer science, the problems can occur because of unawareness of possible outcome of an action or complicated interfaces. Passwords are the perfect example where a problem can occur.

A common user would create an easy-to-remember password such as a birthday date, a pet's name, 000000, etc. This solution is easy for the user, but clearly not secure. In addition, users usually generate passwords following the same behaviour: For instance, the research of the SURPASS novel [2] found that most of the uppercase letters appeared in the first position and that most of the symbols appears at the last position. Consequently, an attacker can use a dictionary attack [2]. The latter consists of understanding this password generation behaviour to create a dictionary of common passwords. Then, the attacker tries these passwords until finding the good one. If the password is too short or too common, it would be broken easily. The attack is even faster if the attacker creates a dictionary containing element of the user's personal life.

Unfortunately, there is another problem, a common user uses many services. How can the user manage his password with several accounts? The solution is simple: using the same password for each account. Again, this solution is easy but not secure. Even if the commonly used password is strong, if, for example, one of the servers, where the common password is used, is compromised by an adversary, then this adversary can also access to the other accounts of the user. To manage to obtain the user's common password, an attacker can use ~~phishing~~ phishing attack [3] or honeypot attack [4]. Phishing attack [3] consists of stealing the identity of a trusted service. ~~Then,~~ the attacker requests personal informations about the user imitating, for example, fake e-mails and fake websites. Honeypot attack [4] consists of creating a service with useful features. Then, if the user registers to this service, the attacker can access to user's password. Sadly, remembering a strong password for each account is too hard for a common user.

An existing solution, which make users use strong and different passwords, is the password manager [5]. This software acts as a ^alocker and store all hard-to-remember passwords. When the user connects to a service, he just needs the key of the locker, called the master password. This solution is really comfortable but not perfect, because it is a single point of failure. Therefore, password manager can still be victims of security vulnerability. For instance, an attacker can install a keylogger [6] on the user's machine. This software saves every keyboard inputs, hence the password too. Consequently, if an attacker manages to find the master password, he has access to all accounts of the user.

Does it exist a perfect solution to provide security and simplicity to a user? This is the purpose of the single password authentication (SPA) protocol. It implements authentication with a third party storage like a cloud or a smartphone. The user only needs a unique password to connect to all his online services. The idea of SPA is to create a different key for each online services, then the user uses his unique password to encrypt it and finally to store it into the storage. Since an attacker needs to access to the password and to the storage, the uniqueness of the password is not a single point of failure. Hence, SPA solves the problem of the password manager [5]. This solution is simple due to the uniqueness of the password. It also provides

security because the online service never learns the user's password or find any way to impersonate him. Furthermore, this solution is not vulnerable to dictionary attack. If an attacker wants to test every possible passwords, it needs to be connected to the storage and to test them in the online service. This problem can be fixed by allowing a small number of attempts to connect. Consequently, since an attack cannot be made offline, dictionary attacks are useless.

This protocol is not the first attempt to provide authentication with single password. example of PAKE is Bellovin and Merritt's Encrypted Key Exchange (EKE) [4] permits to create a secure channel if the client and the server share a password. The problem is that the server learns the user's password. Asymmetric Password-Authenticated Key Exchange (APAKE) [5] is a solution to this problem. The client has a password and the server has a function to verify the password. Unfortunately, this solution is vulnerable to dictionary attack. An attacker can steal the function of the server to test hundreds of passwords. The solution is to authenticate with multiple server. This is the case of SPA which uses a cloud or a mobile storage. The only condition to provide security is that the storage and the server do not interact.

The aim of this project is to implement the four versions of the SPA protocol and compare their performance.

Chapter 2

Cryptography

Before going into the protocol details, it is necessary to introduce some notions of cryptography which are used in the SPA implementation.

Symmetric encryption with one time pad: Encryption with one time pad consists of generating a key k of the same length as the message m . Then, the encryption is made using a simple xor operation:

$$c = m \oplus k$$

Then the message can be easily recovered:

$$m = c \oplus k$$

This encryption is really fast and provides perfect security if it respects three conditions:

- 1) The key as the same length as the message.
- 2) The key is used only once.
- 3) The key is truly random.

Hash: A hash function H computes the fixed-length hash value of a given input of an arbitrary length. A secure hash function can have the following properties:

- 1) H is collision resistant: It is hard to find two messages which have the same hash value.
- 2) H is resistant to the preimage: Given the hash value, it is hard to recover the original input.
- 3) H is resistant to the second preimage: Given the original input, it is hard to find another input with the same hash value.

Digital signature: The digital signature is a cryptographic technique which authenticate the signer of a message. This signature can be based on RSA. Plain RSA signature is vulnerable because an attacker can combine two signatures to create a new valid signature. Hence, the RSA-PKCS#1-V1.5 algorithm is implemented as a digital signature. This algorithm uses a hash function and padding to solve this vulnerability. Imagine that Bob sends a message to Alice and that Alice wants to verify if the message comes from Bob. Alice has the public key of Bob (N, e) and Bob has his private key (d) . Bob signs the message m and then he sends m and the signature s to Alice:

$$s = \text{pad}(\text{hash}(m))^d \mod N$$

Then, Alice can unsign s to authenticate Bob:

$$m' = s^e \mod N = \text{pad}(\text{hash}(m))^{de} \mod N = \text{pad}(\text{hash}(m))$$

Finally, Alice can compute $hash(m)$. If m' contains $hash(m)$ and contains the correct padding format, Alice knows that Bob is the sender of the message.

MAC: The Message Authentication Code (MAC) is used for the authentication between users who share a symmetric key. In this project, we use Hash-based message authentication code (HMAC) [6]. Again, imagine that Bob sends a message to Alice and that Alice wants to verify if the message is sent by Bob. Alice and Bob share a secret key K and use a hash function H . Bob computes the MAC s from the message m and sends them to Alice:

$$s = h((K \oplus opad) || h((K \oplus ipad) || m))$$

$||$ denotes concatenation and opad/ipad denotes a padding of the size of one block. For instance, the block size of SHA-256 is 512 bits.

Then, Alice can compute the MAC with m to obtain s' . If $s = s'$, Alice knows that Bob is the sender of the message.

Blind signature: The blind signature [7] is an extension of the digital signature. It permits to sign a message without revealing the message to the signer. The concept can be hard to understand because it is difficult to guess why a signer would sign a message without knowing it. Let's consider this simple example: Imagine a political party which wants to hold an election. The party wants to authenticate each vote but each elector does not want his vote to be known. The blind signature is a solution to this problem.

In this project, we use a blind signature based on RSA: (N, e) is the public key and (d) is the private key of the RSA signature scheme. The idea is to enclose the message using a blind factor r . Since the signer does not know r , he is unable to read the message.

The original message is represented as $m \in \mathbb{Z}_n$ and the signature as s . First, we add the blind factor $r \in \mathbb{Z}_n^*$ to the message.

$$m' = r^e m \mod N$$

Then, the signer signs the blinded message m' using its private key.

$$s' = (m')^d \mod N = r^{ed} m^d \mod N = r m^d \mod N$$

Finally, we remove the blind factor using the inverse in order to obtain the signature of m .

$$s = r^{-1} s' \mod N = r^{-1} r m^d \mod N = m^d \mod N$$

Blinding attack: Nevertheless, the RSA blind signature is not perfect because it is vulnerable to the blinding attack. This comes from the fact that RSA uses the same key to sign or to decrypt a message. Let's consider an example where Alice is a server. She has a single private key to sign and to decrypt messages. Imagine that Bob sends a message m to Alice using Alice's public key.

$$m' = m^d \mod N$$

Now, imagine that Oscar wants to read this message. If Oscar can intercept the message from Bob and then he can send it to Alice by asking to sign it. Since Alice is using the same private key to sign a message, Oscar gets the original message of Bob.

$$m = m'^d \mod N = m^{ed} \mod N$$

In other words, Alice decrypts the message when she signs it. Therefore, a different key pair must be used for signing and exchanging messages. In this project, we do not use RSA encryption. Therefore, the blinding attack does not concern us.

Oblivious transfer The oblivious transfer [8] is a protocol which permits to exchange data between a client and a server. Let's imagine that the server has n tuples of the form (w_i, c_i) , w_i is an index and c_i is the corresponding data. The particularity of this protocol is that the client can retrieve the data c_j from the index w_j without revealing the value w_j to the server and without learning any value c_i where $i \neq j$.

In this project, the oblivious transfer protocol by Ogata and Kurosowa. Let H be a hash function and G be a pseudo-random generator. We assume that the server has a private key (d) and the client has the related public key (N, e) . The server starts by creating n keys using the indexes w_i .

$$K_i = (H(w_i))^d \mod N$$

Then it uses these keys to encrypt each data c_i in the following way:

$$E_i = G(w_i \| K_i \| i) \oplus (0^l \| c_i)$$

To execute the xor, each part must have the same length. Hence, the server adds zeros in front of c_i to respect this property. Concretely, l is the length of the output of G minus the length c_i . Then, the server sends every E_i to the client. Now, let's consider that the client wants to retrieve data c_j . Using blind signature, the client is able to reconstruct the key K_j corresponding to w_j . So, using a blind factor r , the client generates:

$$Y = r^e H(w_j) \mod N$$

Then, the client asks to the server for a blind signature. This way, the server cannot learn the value w_j chosen. At the end, the client received the value:

$$K_j = r^{ed} H(w_j)^d \mod N = H(w_j)^d \mod N$$

Finally, he can decrypt the corresponding data using:

$$(a_i \| b_i) = E_j \oplus G(w_j \| K_j \| i)$$

If $a_i = 0^l$, b_i corresponds to the data wanted by the client. Since, the client has only one K_j , he can only decrypt the data c_j corresponding to w_j . So, he cannot learn any other value of c_i with $i \neq j$.

Chapter 3

Protocol Description

The single password authentication protocol (SPA) [9] lets a client (Alice) to connect to every website (Bob) using the same password. The password is used to encrypt a secret stored in an untrusted storage or a trusted mobile device (Carol).

3.1 Overview

First, Alice invents a username and a password which must be as strong as possible: ~~it~~ must look like random. These will be used for each website Alice wants to connect to and Alice needs to remember them.

the password

Registration: When she registers to Bob, she generates a secret key sk which is used to connect Bob later (it can be considered as a password to connect to Bob). She sends her username and sk to Bob. Then, Alice registers to Carol. She generates an id and she uses her password to encrypt sk . Finally, she sends her id and sk encrypted to Carol. At that point, Alice only needs to remember her username and her password.

Connection: When Alice wants to connect to Bob, she first needs her username and her password. She uses the username to obtain a challenge from Bob. Then, Alice generates id again and sends it to Carol to recover sk encrypted. Now, Alice can decrypt sk and calculate the response of the challenge. Then Alice sends it to Bob. Finally, Bob verifies the response and accepts the connection if it is correct.

SPA describes four different protocols: server optimal cloud SPA, storage optimal cloud SPA, privacy optimal cloud SPA and mobile SPA.

3.2 Server optimal cloud SPA

Registration (Figure 1): First, Alice generates two RSA key pairs. (ssk, svk) for the digital signature used with Bob and (bsk, bvk) for the blind signature used with Carol. To register to Bob, Alice sends him her username and svk . Then, to register to Carol, Alice starts by signing her password with bsk to get the signature $sig = BSign(bsk, Hash(pwd))$. Then, she uses sig to encrypt ssk and to obtain $ctext = Encrypt(Hash(sig), ssk)$. Then, Alice generates an $id = Hash(Alice, Bob)$. Finally, Alice sends to Carol id , bsk and $ctext$. Now, she can forget everything except her username and her password.

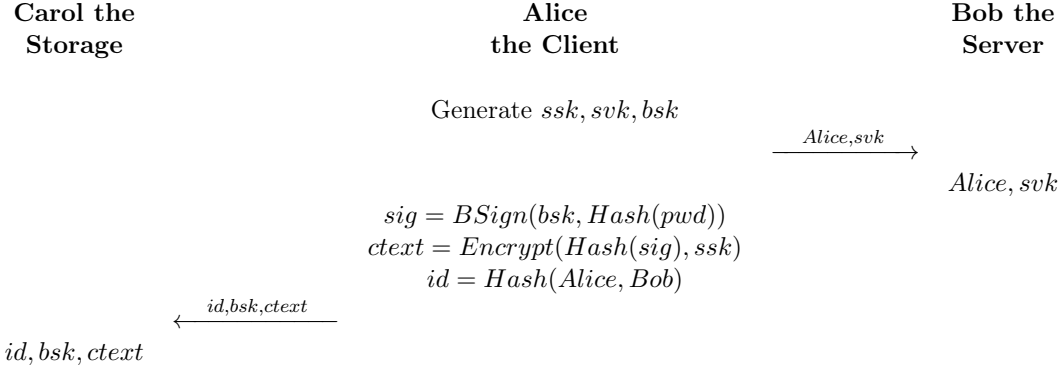

Figure 1: Server optimal cloud SPA registration

Connection (Figure 2): When Alice wants to connect to Bob, she only sends to him her username and gets a challenge from Bob. Then, Alice must recover ssk to compute a response. She begins by recovering her $id = Hash(Alice, Bob)$ and sends it to Carol. She asks Carol to sign her password by using a blind signature scheme (BS): $sig = BSign(bsk, Hash(pwd))$. Finally, Carol sends to Alice $ctext$. Now, Alice has sig and $ctext$, so she can compute $ssk = Decrypt(Hash(sig), ctext)$. Then, she can compute the response R and sends it to Bob which accepts if it is correct.

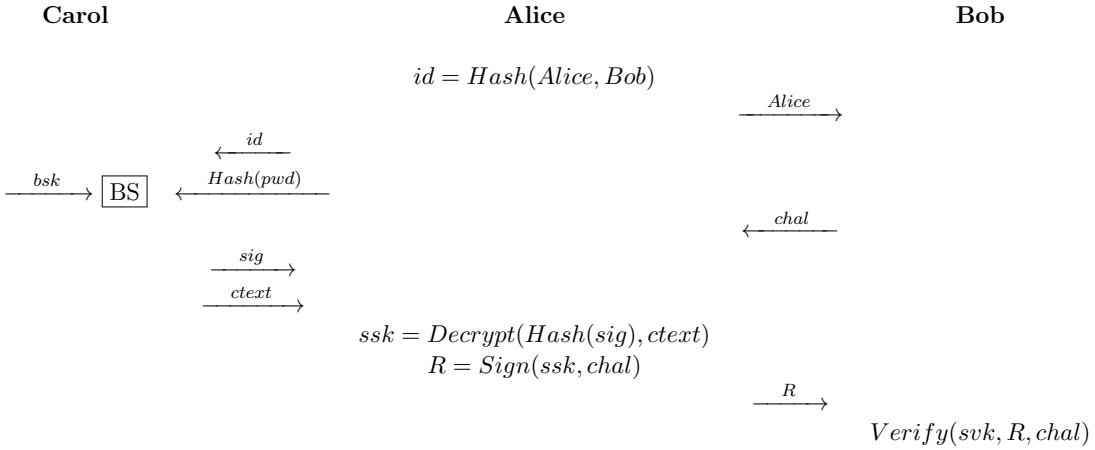

Figure 2: Server optimal cloud SPA connection

This version of the protocol is the most efficient for the server. If Bob is malicious, Alice is safe because Bob never learns Alice's password. Furthermore, challenge-response is used for each connection, hence, Bob cannot make a dictionary attack. If Carol is malicious, Alice is not anonymous nor unlinkable. Alice is not anonymous because Alice's username is calculated using $Hash(Alice, Bob)$. So Carol can make a dictionary attack to find it. Furthermore, Alice is linkable by linking the found username with the id provided.

3.3 Storage optimal cloud SPA

Registration (Figure 3): As Server optimal cloud SPA, Alice first generates two RSA key pairs (ssk, svk) and (bsk, bvk) . To register to Bob, Alice sends him the username, svk and bsk . Then, to register to Carol, Alice begins by generating her $id = BSign(bsk, Hash(pwd))$. Then, she encrypts ssk with her password to get $ctext = Encrypt(Hash(pwd), ssk)$. Finally, Alice sends id and $ctext$ to Carol.

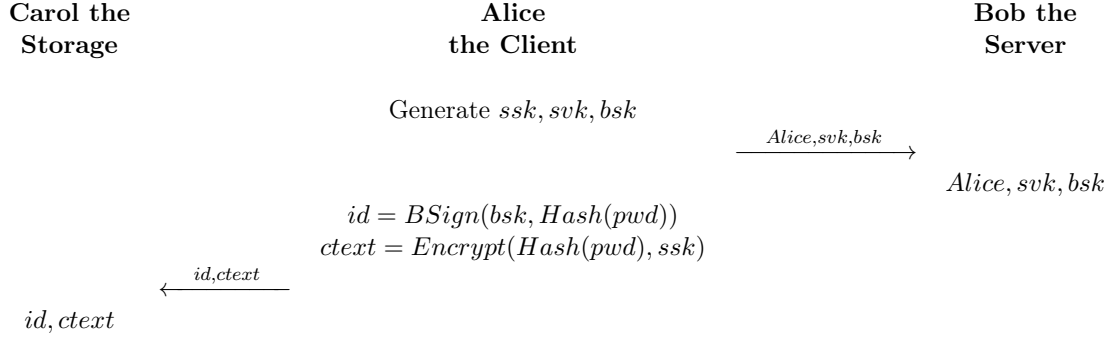

Figure 3: Storage optimal cloud SPA registration

Connection (Figure 4): When Alice wants to connect to Bob, she first sends him her username. Then, she asks Bob to sign her password (BS): $id = BSign(bsk, Hash(pwd))$. Finally, Bob sends Alice a challenge. Then, Alice needs ssk to compute the response. Now, she has recovered her id. She sends it to Carol and Carol sends her the corresponding $ctext$. Then, Alice can recover $ssk = Decrypt(Hash(pwd), ctext)$ and compute the response $R = Sign(ssk, challenge)$. At the end, Alice sends the response to Bob which accept Alice if it is correct.

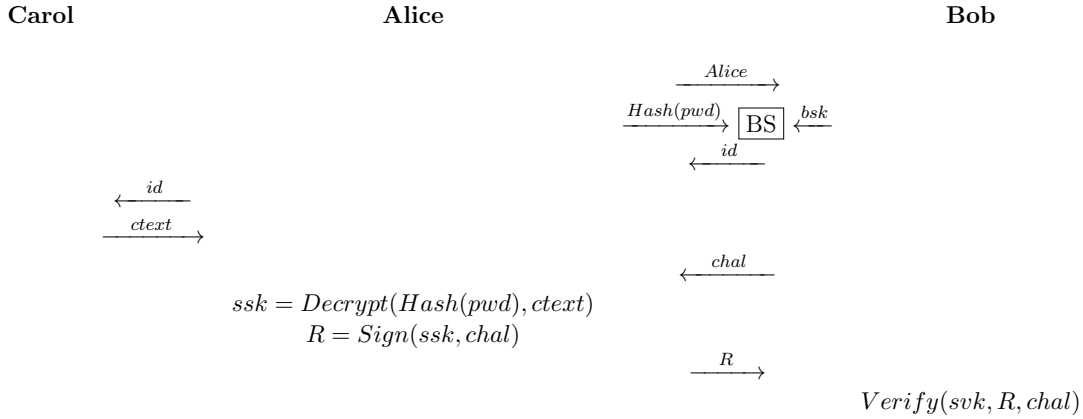

Figure 4: Storage optimal cloud SPA connection

This protocol is the most efficient for storage. If Bob is malicious, Alice is safe like the server optimal protocol. If Carol is malicious, Alice is anonymous but still linkable. Alice is anonymous because Alice's id is a signature. Hence, Carol cannot recover the id using a dictionary attack. Alice is linkable because Carol still has access to the id. As server optimal, Bob never learns Alice's password, so Alice is also protected against a dictionary attack from Bob.

3.4 Privacy optimal cloud SPA (Figure 5)

Privacy optimal protocol is the same as storage optimal. Privacy means that this protocol provides anonymity and unlinkability from Bob and Carol. The only difference is made during the connection because Alice and Carol use oblivious transfer (OT). Carol is the sender and Alice the receiver. Alice uses her id and Carol the database contents. At the end, Alice retrieves $ctext$. If Bob is malicious, Alice is safe like the storage optimal protocol. If Carol is malicious, Alice is anonymous and unlinkable. Alice is anonymous because the Alice's id is a signature. Then, Alice is unlinkable because Carol never learns the id of Alice due to oblivious transfer.

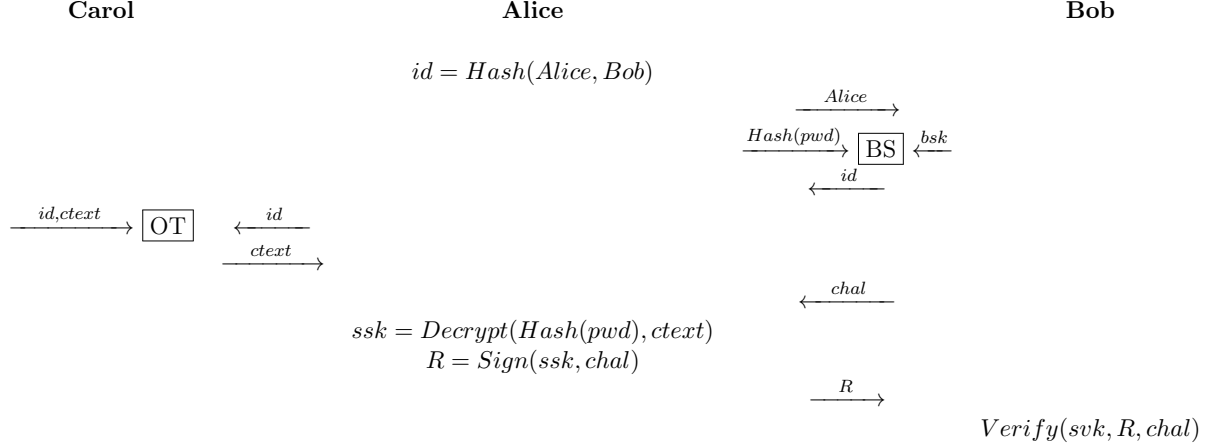

Figure 5: Privacy optimal cloud SPA connection

3.5 Mobile SPA

Mobile SPA does not require a cloud storage. It uses a trusted mobile device instead. The name of Carol is kept to describe the mobile device. This protocol requires a connection between Alice and Carol. It can be a direct internet connection (SSL) or an indirect internet connection (Bluetooth, Wi-Fi, USB). Carol must also be able to display and analyze a human-readable information, like a QR code or a sound. The main advantage of this protocol is that Alice can connect to any terminal, even untrusted. Indeed, she types the password on her mobile. Consequently, the untrusted terminal is unable to obtain the password. However, the mobile can be lost or stolen. In this case, Carol becomes malicious. Fortunately, the data stored is encrypted. So, an attacker does not have access to Alice's secret. In addition, Alice's username is not stored in the mobile. Hence, Alice is anonymous and unlinkable to an attacker. In addition, if Bob is malicious, he never learns Alice's password and cannot mount a dictionary attack since each connection uses challenge-response.

Registration (Figure 6): Alice starts by generating a symmetric key K . To register to Bob, she sends him her username and K . Then, to register to Carol, Alice encrypts K using her password: $ctext = Encrypt(Hash(pwd), K)$. Now, Alice can forget everything except her username and her password.

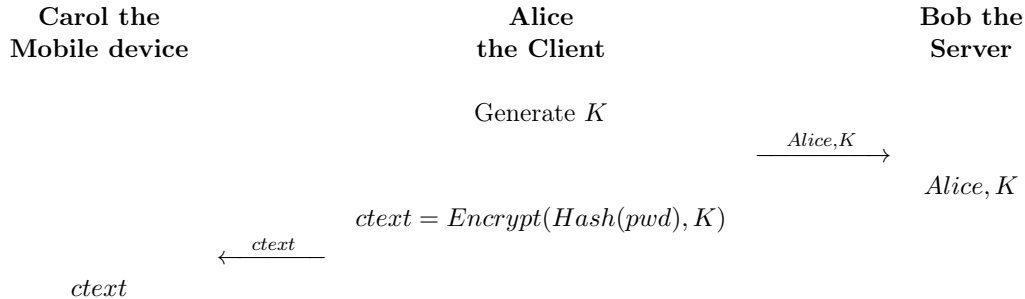

Figure 6: Mobile SPA registration

Connection (Figure 7): When Alice wants to connect to Bob, she first sends him her username to get a challenge. This challenge can be sent to Alice (QR code or audio file) or directly to Carol (SMS). If the challenge is sent to Alice, she uses her mobile device to read it.

Then, Alice provides her password to Carol. Now, Carol can recover $K = \text{Decrypt}(\text{Hash}(\text{pwd}), \text{ciphertext})$ and computes the response $R = \text{MAC}(K, \text{challenge})$. Carol shortens the response using a *TRIM* function and displays it to Alice. Now, Alice can provide R to Bob which verifies it and accept the connection if it is correct.

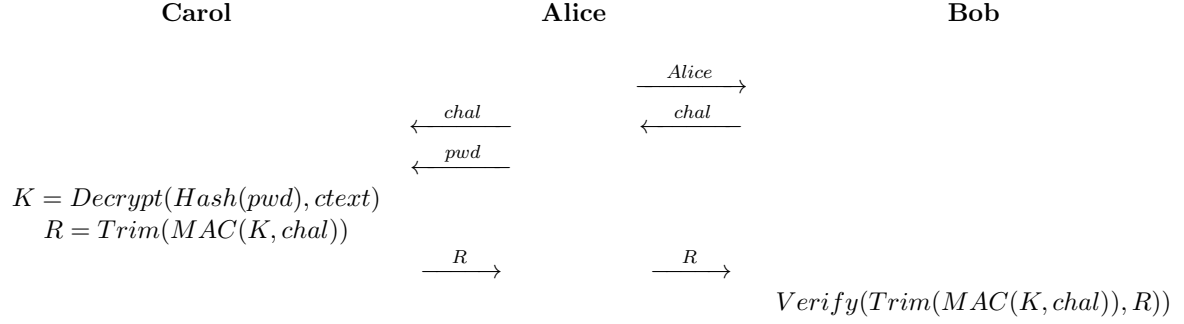

Figure 7: Mobile SPA connection

Chapter 4

Implementation

I decided to implement this project in Java. This programming language is really complete and offers a wide range of libraries and documentation. Since this project requires many features (socket programming, website creation, cryptographic elements, user interface conception, mobile application), Java is one of the best choice. Furthermore, it is the programming language I feel the most comfortable with. I started my implementation by creating my own cryptographic library.

4.1 Cryptographic library

Symmetric algorithms The first type of algorithms implemented are contained in the `SymmetricEncryption.java` class. It implements functions to encrypt, decrypt or MAC a given message using a symmetric key. The symmetric encryption used is one time pad. It is very fast since it uses one xor operation. It also gives perfect security because:

- We use uniformly distributed random key
- Every message in SPA protocol is encrypted with a new key
- The key size and the message size are the same.

Regarding MAC, the implemented algorithm is HMACSHA256. It generates MAC efficiently and in a very secure way.

Asymmetric algorithms The second type of algorithms implemented are contained in `AsymmetricEncryption.java` class. This class only implements RSA. The choice of this algorithm comes from the fact that blind signature can be based on it. So, the class contains functions to encrypt, decrypt, sign and verify the signature of a message. It also implements functions for blind signature: generating a random blind factor, blind and unblind a message. Like, `SymmetricEncryption.java`, there exist libraries [10] to implement these functions. Nevertheless, I prefer to make my own implementation. It makes the code more readable and it permits to understand in details how blind signature is implemented.

Key generation: Encryption can be relatively easy to implement, but key generation is more sophisticated. Therefore, I decided to generate keys using the existing java libraries [10] in `MyKeyGenerator.java` class. So, the generation is secure and efficient. Concretly, AES, RSA and HMACSHA256 keys are generated using these libraries. The key of one time padding is generated using a secure random generator [11]. Each key can be generated in three ways: from random, from a password or into a file which includes the key.

Hash The class `Hash.java` implements SHA256 using java libraries [10]. SHA256 provides the right balance between security and performance.

Oblivious transfer Since oblivious transfer is used by a server and a client, I did not choose to create a static library. I created two objects OTSender and OTReceiver which can be instantiated by a server and a client to execute the oblivious transfer protocol. OTSender needs a Map with w_i the keys and c_i the corresponding data. It also requires an RSAPrivateKey. OTSender automatically generates the keys K_i when it is instantiated. Then, it provides two functions. One to encrypt the data using K_i by generating E_i and one to generate K_j from the index Y received from the client. OTReceiver needs an index w_j and an RSAPublicKey to be instantiated. Then, it provides four additional functions. The first one blinds the index using a given blind factor r to generate Y . The second one unblinds the value K_j received by the server. The third one is used to decrypt the data E_i received by server using K_j . And finally, the last one checks the data generated during the decryption to find and return the corresponding value.

4.2 Implementation of the storage

Database connection: After implementing the necessary cryptographic components, the next step was to find an efficient database for the storage. This database must have many properties. It must be free, fast and it must offer a performance report. I chose to use the SQL database of the Microsoft Azure platform [12]. It is free for academic purposes [13]. It is fast because their servers are available in Europe. Furthermore, their platform automatically provides many statistics about the database. The only disadvantage is the storage size since only 35 MB is available. In the concern of this project, it is enough, since any user store only a small amount of data.

The implementation has two parts: SQL and java. The SQL part means creation of tables and testing queries. I created two tables. Storage_server_optimal for the server optimal protocol. It contains three columns (id, bsk and ctext), each one has type varbinary(256) to store 2048 bits:

id	bsk	ctext
0x582A749BFF...	0x80128461BB...	0x4816B4F323...
0x769398B3F3...	0x68154A3FF1...	0x729BA5BB72...

Storage_storage_optimal for storage optimal and privacy optimal protocols. It contains two columns (id, ctext), each one is also of type varbinary(256):

id	ctext
0x549748104A...	0x6381036A24...
0x32F38BA233...	0x67C7471B31...

The SQL code can be found in the SQLCommands.txt file.

The java implementation is done using the JDBC library [14] created by Oracle and modified by Microsoft for their database. I provide database connection with an object written in the DatabaseConnector.java class. When the object is instantiated, the user provides which protocol he uses and then the corresponding connection is automatically created with the database. Then, I provide functions to execute SQL queries: insertion, search and deletion. For privacy optimal protocol, I also provide a function to fetch every elements of the table in a random order.

Connection between storage and client: When the database was fully implemented, the user must be able to send and retrieve data. Of course, a simple database does not provide features like blind signature or oblivious transfer. So, I first implemented a server for the storage. This server, contained in the Storage.java class, offers an interface between the client and the database. It only includes a main method which creates an SSL socket and wait for a

client connection. When the server starts, it creates a pool of 20 executors [15], so 20 clients can connect at the same time. When a client wants to connect, the server executes one of the existing thread which takes care of him.

This server uses two enumerations to classify each client. The first one is in ProtocolMode.java class. It contains 4 elements: Server_optimal, Storage_optimal, Privacy_optimal and Mobile. These represent each protocol of chapter 3. Of course, Mobile is not used in this implementation since this protocol does not require a storage. However, it is useful for the implementation of the website.

The second enumeration is found in ClientToStorageMode.java. It contains 2 elements: Store and Retrieve. These represent the possible user action: Store during the registration phase and Retrieve during the connection phase.

The thread which takes care of a client is contained in ClientAdministratorThread.java. It first receives the user protocol and the user action. Therefore, it identifies the client and acts consequently:

Server_optimal and Store: The thread receives *id*, *bsk* and *ctext* and stores them in the database.

Server_optimal and Retrieve: The thread receives *id* and *Hash(pwd)*, fetches *bsk* and *ctext* from the database and uses the blind signature scheme to send *sig* and *ctext* back.

Storage_optimal and Store: The thread receives *id* and *ctext* and stores them in the database.

Storage_optimal and Retrieve: The thread receives *id*, fetches *ctext* from the database and sends it back.

Privacy_optimal and Store: The thread receives *id* and *ctext*, stores them in the database and sends the public key for oblivious transfer back.

Privacy_optimal and Retrieve: The thread receives *id*, fetches the Storage_storage_optimal table and uses oblivious transfer to send *ctext*

When the server-side of the storage was implemented, I implemented the corresponding client-side. It is contained in the StorageClient.java class. This object acts as an interface for the user. When it is instantiated, it offers two methods: one to store data into the storage during the registration phase and one to retrieve the data during the connection phase. This object contains two constructors: one for the Server_optimal protocol and one for the Storage_optimal and Privacy_optimal protocols.

Data storage: When the client wants to store data, this object creates an SSL connection and runs two threads. One to send the data (ClientSenderThread.java) and one to receive a response from the server (ClientReceiverThread.java). These threads are executing with a single executor [15] to avoid parallelism errors.

In the Server_optimal implementation, the client sends *id*, *bsk* and *ctext* and receives an acknowledgement.

In the Storage_optimal implementation, the client sends *id* and *ctext* and receives an acknowledgement.

In the Privacy_optimal implementation, the client sends *id* and *ctext* and receives the public key for oblivious transfer.

Data retrieval: When the client wants to retrieve the data, the object also creates an SSL connection but this time, it runs one thread (ClientRetrieverThread.java). This thread fetches the data from the server computes and returns the private key *ssk* wanted by the client.

In the Server_optimal case, the client sends *id*. Then, he executes the blind signature scheme to obtain *sig*. Finally, he receives *ctext* and computes *ssk*.

In the Storage_optimal case, the client sends *id*, receives *ctext* and computes *ssk*.

In the Privacy_optimal case, the client sends *id*. He uses oblivious transfer to obtain *ctext* and computes *ssk*.

4.3 Implementation of the mobile application:

The mobile protocol requires a mobile application. I chose to develop it on Android. This platform is based on java and has a lot of documentation. For this project, this application must read a challenge and display the response to the user. Since Google provides a free and well-documented API to read barcodes [16], I decided to display the challenge as a QR code. The application uses its camera to read it and to display the response on the screen.

I first cloned a basic application from the official github repository of Google [17]. This application permits to take a picture using the camera and to display its data. Then, I modified the code to work with this project. When the user starts the application, he first needs to enter his password. Then, like the cloud-based protocols, he can either register to the website or connect to it.

If the user wants to register to the mobile application, he has to enter the IP address of its computer. This IP address will be given by the computer software. Then, an SSL connection is opened between the mobile application and the computer software. The latter automatically sends *ctext*. Finally, the android application displays a pop-up to tell the user if the registration has succeeded. Concretely, the application writes *ctext* into a file and store it in the smartphone storage.

If the user wants to connect to the website, the application starts to scan a QR Code. When it finds a QR Code, it recovers the challenge from it, computes and displays the response. This is done without any user interaction, contrary to the original application.

4.4 Implementation of the website:

Developping website in Java: Java permits to create a website using Java EE [18]. I used this platform to create a dynamic website. *Html* pages are generated using *jsp* files, a format similar to *php*, and the management of these files are made using a java object called a *servlet* [19]. Concretely, if a user connects to a precise link, he does not directly obtain the corresponding *html* file. The link is related to a servlet which treats the request, generates the response and return a *jsp* file. This implementation provides security against vulnerabilities like cross-site scripting (XSS) [20].

Website access: In this project, the website is accessed in two ways. If the user wants to register or to obtain a challenge, he will use the computer software. If the user wants to submit the response, he will use his web browser. Consequently, I implemented two java servlets. The first one is contained in RegistrationServlet.java, it is related to the url: <https://128.178.73.85:8443/pro/register> and can only be accessed from the client

software because it only implements the http post request. When a user wants to register, this class checks the values received and create a new client. When a user wants to connect, this class checks if the user is registered and sends him a challenge. The second one is contained in ConnectionServlet.java, it is related to `https://128.178.73.85:8443/pro/connect` and can be accessed from a web browser. When the user wants to connect, he needs to give a username and the response of the challenge. If the response is correct, the servlet generates a new page to show the user that he is connected.

Client management: The web-server also implements a class to represent a client. This class is contained in Client.java. A client can be instantiated using three constructors: one for Server_optimal protocol, one for Storage_optimal protocol and one for Mobile protocol.

In the case of Server_optimal, the client is instantiated with a *username* and his public key *svk*.

In the case of Storage_optimal, the client is instantiated with a *username*, his public key *ssk* and his private key for blind signature scheme *bsk*.

In the case of Mobile, the client is instantiated with a *username* and his secret key *K*.

Note that there is no difference between Storage_optimal and Privacy_optimal for the server. Therefore, both are represented with the Storage_optimal protocol.

This class also implements an enumeration to represent the state of the client. When the client is created, his state is set to *REGISTERED*. When a challenge is sent to the client, his state is set to *READYTOAUTH* and finally, a client which provides the good response is set to *AUTH*. Furthermore, like the implementation of the storage, the web-server uses the ProtocolMode.java class to enumerate each possible protocol. Finally, the class implements other functions: one to set a challenge to a registered client, a getter for each value of the client and one to change the state. More details can be found in the JavaDoc provided with my code. The website generates a dynamic Map to store the connected clients. The username are used as keys and the client objects are the corresponding values.

Website deployment: When the website was developped, it was exported in a WAR file [20]. Then Apache Tomcat [21] was installed on the web-server. This software uses the WAR file to implement the website and to run it.

Client-side of the website: When the server-side of the website was implemented, I implemented the corresponding client-side. This part is really similar to the client-side of the storage. The only difference is that the request are sent using HTTP request [22]. This implementation is contained in ServerClient.java. It contains three constructors, one for each protocol used by the server. Furthermore, this object provides two methods: one to register to the website and one to get a challenge.

When the user wants to register to the server, the object creates a new thread (ClientSenderThread.java) which sends the data to the server. Then, the thread waits for an acknowledgement and return it.

In the Server_optimal implementation, the client sends *username* and *svk*.

In the Storage_optimal implementation, the client sends *username*, *svk* and *bsk*.

In the Mobile implementation, the client sends *username* and *K*.

When the user wants to obtain a challenge, the object also creates a new thread. The latter sends the username, waits for a challenge and returns it.

In the `Server_optimal` implementation, the client sends *username* and receives a challenge.

In the `Storage_optimal` implementation, the client uses blind signature scheme to blind his password. Then, he sends *username* and *password* and receives *id* and a challenge.

In the `Mobile` implementation, the client does not connect using the client software. He simply types his username on the website to obtain the challenge in the form of a QR Code.

4.5 Note on SSL implementation:

In a normal implementation of SSL, the server sends its public key and a certificate to the client. The latter checks that the certificate is trusted by a certification authority. In this project, the RSA key pairs used are self-generated. Hence, an external user cannot trust my certificate and must reject the connection. For this reason, the certificate is stored within the project to accept the connection.

For the connection with the storage and the android application, I use SSL socket [23] to create my own secure connection in an unused port. I get the certificate from a file to create it. This implementation can be found in `SSLClientUtility.java` and `SSLServerUtility.java`. These classes are inspired from [24].

For the connection with the website, I cannot create my own connection since https works with port 8443. Consequently, the certificate must be imported inside the Java Virtual Machine (JVM) and the web-browser.

4.6 Implementation of the user interface:

When the website was implemented, I implemented a user interface. This interface is necessary for two reasons: First, it permits to send and retrieve data with the storage. Second, it is a user-friendly way to interact with the server. For instance during the connection phase of the storage optimal version of the protocol, the user gives his password to this user interface and then the blind signature scheme is invisible for him. This interface is implemented using SWT [25], it permits to design a basic interface easily. It contains four input fields: one to select the protocol, one to type the username, one to type the password and one to select the website. Then, it contains two buttons: one to register and one to connect. Finally, it contains two outputs: one to display a QR code if the mobile protocol is used and one to display informations, so that the user understands what happens.

Registration: When the user wants to register, he first needs to fill the different input fields. Then, when he clicks on the register button, the software instantiates two objects: `ServerClient` and `StorageClient`.

When the `Server_optimal` protocol or the `Storage_optimal` protocol is selected, the software simply registers to the server and to the storage using the corresponding methods.

When the `Privacy_optimal` protocol is selected, the software registers to the server and to the storage. In addition, it receives the public key for oblivious transfer and store it into a file.

When the `Mobile` protocol is selected, the software registers to the server, displays its IP address and waits for a connection with the android application.

Connection: When the user wants to connect, he clicks on the connect button. Like registration, the software instantiates `ServerClient` and `StorageClient`.

When the `Server_optimal` protocol is selected, the software retrieves the *ssk* from the storage and obtains a challenge from the server using the corresponding methods. Then, it computes the response and copy it into the clipboard. Finally, it display a message to tell the user that he can connect on the website.

When the `Storage_optimal` protocol is selected, the software retrieves *id* from the server and obtains a challenge. Then, it uses this *id* to retrieve *ssk* from the storage. Finally, it computes the response and copy it into the clipboard.

When the `Privacy_optimal` protocol is selected, the software retrieves *id* from the server and obtains a challenge. Then, it recovers the public key for oblivious transfer from the file. Then, it uses this key and *id* to retrieve *ssk* from the storage. Finally, it computes the response and copy it into the clipboard.

When the `Mobile` protocol is selected, the software obtains a challenge from the server. Then, it computes a QR code and displays it. Finally, the response can be computed using the android application.

Chapter 5

Performance

Now that the four protocols are implemented, I compared their performance. To compute the performance of each protocol, three times are calculated: the time used during the registration phase (Figure 1,3,6) or the connection (Figure 2,4,5,7) between the client and the website (Alice-Bob), the time used during registration or connection between the client and the storage (Alice-Carol) and finally the total time used for registration or connection. The registration time represents the time needed to send data to the storage or the website. The connection time represents the time needed to retrieve the data and compute the response. The total time represents the overall time considering client-server connection and the necessary computations. The following arrays display the average time between 25 tests in milliseconds when the RSA key-length is 1024 bits. The database is empty when the first test is launched

Server optimal: Here is an array representing the average time for the server optimal protocol:

	Alice-Bob	Alice-Carol	Total
Registration	15	35	50
Connection	22	218	245

During the registration phase, we see that the registration lasts longer with Carol. This result is not surprising. Indeed, to register with Carol, Alice must compute *sig*, *ctext* and *id* before sending the data. When Alice registers with Bob, she just needs to send *svk*.

During the connection phase, the connection lasts longer with Carol. Once again, this result is not surprising. When Alice retrieves the data from Bob, she uses the blind signature scheme, contrary to the connection with Bob which only requires to receive a challenge.

Connection requires more calculations than registration, this is why the total time of the connection is bigger than the sum of the connection time between Alice and Bob and the connection time between Alice and Carol. Nevertheless, this extra time is insignificant.

Storage optimal: Here is an array representing the average time for the storage optimal protocol:

	Alice-Bob	Alice-Carol	Total
Registration	29	36	65
Connection	237	41	284

During the registration phase, we see that the registration lasts a bit longer with Carol. Like the server optimal protocol, this result is not surprising because Alice must do some computations before sending the data to Carol.

During the connection phase, the connection lasts longer with Bob. Once again, this result is normal. In the storage optimal protocol, the blind signature scheme is used with Bob and not with Carol. This requires more computations and consequently more time.

Like server optimal, connection requires more calculations than registration, this is why the total time of the connection is bigger than the sum of the connection time between Alice and Bob and the connection time between Alice and Carol. Nevertheless, this extra time is insignificant.

Privacy optimal: Here is an array representing the average time for the privacy optimal protocol and the corresponding plot (Figure 8):

	Alice-Bob	Alice-Carol	Total
Registration	26	38	64
Connection (0 element)	225	48	279
Connection (200 elements)	218	277	505
Connection (500 elements)	223	1773	2004
Connection (1000 elements)	229	3164	3407

Figure 8: Plot of privacy optimal performance

Chapter 6

Implementation

something wrong here?

The privacy optimal protocol is similar to the storage optimal protocol. When the storage is empty, the result is really close to storage optimal. But, due to the oblivious transfer, the storage needs to send all its data to the client. Bigger the database is, longer the connection will last. We see this result in the array: when the storage has a thousand clients, the connection lasts more than three seconds.

Mobile: Here is an array representing the average time for the mobile protocol:

	Alice-Bob	Alice-Carol	Total
Registration	21	127	148
Connection	15	1362	-

Computing the performance of the mobile protocol is more complicated since it requires more user interactions. During the registration phase, the time to register with the storage is calculated when the user enters the correct IP address. We see that the registration with the server is really similar to server optimal. This is not surprising since Alice only sent her username and her key to Bob. The registration with the storage is longer, this shows that a connection with a smartphone lasts longer.

The connection time is calculating directly on the server and on the smartphone. It represents the time that the server needs to generate a challenge and the time that the smartphone needs to read this challenge a compute the response. We see that generating a QR code is really fast. In addition, reading the QR code and compute the response lasts much longer. This result is not surprising since launching the smartphone camera is a long process.

When Alice wants to connect, she needs to use her smartphone to read the QR code. Since this user interaction is not mesurable precisely, I do not consider the total time for this protocol.

2048 bits length-key: Here is an array representing the average connection time for the server optimal and storage optimal protocol, both requires blind signature and digital signature with an RSA key-length of 2048 bits:

	Alice-Bob	Alice-Carol	Total
Server optimal	23	258	287
Storage optimal	282	43	338

As expected, a connection with a longer key increase the connection time. Nevertheless, this increase is quiet small and reasonable.

Personal conclusion: From the result above, the difference between 1024 and 2048 RSA key-length is small. To enforce security, I think that 2048 bits key-length should be used. In addition, server optimal and storage optimal have fast and similar results. However, I think that storage optimal is better because it provides anonymity if Carol is malicious. Then, Privacy optimal enforces privacy but the connection time increases quickly. Consequently, the storage becomes vulnerable. An attacker can register a thousand times to the storage to decrease its performance. Consequently, I think that this protocol is not usable. Finally, the mobile protocol is longer than server optimal or storage optimal. However, this protocol is still fast and it permits to connect from any terminal. Hence, this protocol should also be used.

Chapter 7

Conclusion:

The single password authentication (SPA) protocol permits a user to connect to many services using a unique password. It consists of using a third party to authenticate. It requires either an untrusted external storage (Cloud SPA) or a trusted smartphone (Mobile SPA). This protocol contains four versions which provide different levels of performance and privacy.

If you say "security" instead of privacy, people can misunderstand and think that the problem related to password security.

- α ~~security~~ **privacy**. Indeed, the user is not anonymous nor unlinkable if the storage is malicious.
- α Storage optimal cloud SPA is the most efficient for the storage. It is more ~~secure~~ **private** than the server optimal version. Indeed, if Carol is malicious, it provides anonymity to the user, who is, however, still linkable.
- α Privacy optimal cloud SPA is ~~the most secure~~ **secure and private** for the user. In fact, it provides anonymity and unlinkability if Carol is malicious. Unfortunately, efficiency decreases quickly if the storage contains many data.

Mobile SPA permits to connect to anywhere, especially if the terminal used is untrusted. This protocol provides anonymity and unlinkability even if the smartphone is stolen. In addition, it is still efficient but it requires more user interactions.

These protocols were implemented in Java following five main steps. The first one consisted of creating a cryptographic library. It collects all the necessary algorithms required by the protocol: -It contains an implementation of one time pad and HMacSHA256 for symmetric encryption and MAC.

-It implements RSA for encryption, digital signature and blind signature for asymmetric encryption.

-It implements useful functions to create, store and retrieve keys.

-It contains an implementation of the SHA256 hashing algorithm

-It contains an implementation of two objects to use oblivious transfer.

The second step consisted of creating a cloud storage. The latter is a Java software connected to an SQL database. This database contains two tables: one for server optimal and one for storage and privacy optimal. Then, the Java software provides an interface to store and retrieve data from this database following each protocol requirement.

The third step consisted of creating an Android application to be used with the mobile version of the protocol. This application is based on an existing QR code reader. It was modified to create an SSL connection with a Java software when the user registers and to read a challenge

add new line

cryptographich

contained in a QR code and display a response when the user connects.

The fourth step consisted of implementing a basic website. It represents the service the user wants to connect to. This website was implemented using Java EE. It offers two possible accesses: from a Java software if the user wants to register or get a challenge or from a web browser if the user wants to connect. This website provides a simple connection interface and displays the actual state of the user: "Connected!" if the connection succeeds and "Not connected" or "Not registered" otherwise.

Finally, the last step consisted of creating a Java client software. This software permits to connect to the storage or to the website using SSL connection. Then, it provides an SWT interface to the user. The latter can enter his username and his password, then he can select a website and a protocol to register or to connect. When this interface gets all the necessary data from the user, it automatically executes the corresponding action. The execution follows the protocol requirement and is invisible for the user.

After the implementation, each protocol's performance was tested. This test computes different registration and connection times: the time between the client and the storage, the time between the client and the website and finally the total execution time. These tests show that server optimal and storage optimal have similar results. They also permit to see that privacy optimal becomes unusable when the amount of data in the storage increases. The performance was also tested when the RSA key-length is 2048 instead of 1024. This test shows that the 2048 bits key is slower than the 1024 bits key. However, the total time is still acceptable. Consequently, using 2048 bits key is a good solution. Finally, the total time of the mobile protocol was not computed because it requires user interactions. Consequently, only the time between the smartphone and the client and the time between the client and the website were calculated. The result shows that this protocol is fast and perfectly usable.

Finally, we see that SPA can facilitate the user authentication process. Unfortunately, the most secure version of the protocol is not perfect because the connection can be very slow. This comes from the fact that all the data is sent during oblivious transfer. Consequently, the next step can be to improve oblivious transfer or to replace it with another transfer scheme. This improvement can reduce the amount of time required by privacy optimal. This would be the perfect compromise between security and speed.
